CREDIBLE LOSS RATIO CLAIMS RESERVES: THE BENKTANDER, NEUHAUS AND MACK METHODS REVISITED

BY

WERNER HÜRLIMANN

ABSTRACT

The Benktander (1976) and Neuhaus (1992) credibility claims reserving methods are reconsidered in the framework of a credible loss ratio reserving method. As a main contribution we provide a simple and practical optimal credibility weight for combining the chain-ladder or individual loss ratio reserve (grossed up latest claims experience of an origin period) with the Bornhuetter-Ferguson or collective loss ratio reserve (experience based burning cost estimate of the total ultimate claims of an origin period). The obtained simple optimal credibility weights minimize simultaneously the mean squared error and the variance of the claims reserve. We note also that the standard Chain-Ladder, Cape Cod and Bornhuetter-Ferguson methods can be reinterpreted in the credible context and extended to optimal credible standard methods. The new approach is inspired from Mack (2000). Two advantages over the Mack method are worthwhile to be mentioned. First, a pragmatic estimation of the required parameters leads to a straightforward calculation of the optimal credibility weights and mean squared errors of the credible reserves. An advantage of the collective loss ratio claims reserve over the Bornhuetter-Ferguson reserve in Mack (2000) is that different actuaries come always to the same results provided they use the same actuarial premiums.

KEYWORDS

Claims reserve, loss ratio method, credibility method, minimum mean squared error, minimum variance, chain-ladder, Cape Cod, Bornhuetter-Ferguson reserve, Benktander reserve, Neuhaus reserve

1. INTRODUCTION

The design of our new claims reserving method is inspired from and similar but different from the Benktander method reviewed in Mack (2000), Section 2. While Mack worked for simplicity in the context of a single origin period (accident year or underwriting year), our approach is based on a full loss
development triangle of paid claims (or alternatively incurred claims) with several origin periods. As in other methods we require additionally the knowledge of a measure of exposure like premiums for each origin period.

The standard claims reserving methods include the commonly used reserving methods as the Chain-Ladder, the Cape Cod and the Bornhuetter-Ferguson methods (consult the Swiss Re brochure by Boulter and Grubbs (2000) for a useful elementary description of these methods). While the standard methods apply the so-called chain-ladder factors defined by link ratios (average ratio of cumulative paid claims between two consecutive development periods) our approach is based on loss ratios (average ratio of incremental paid claims to exposure for each development period). The main contribution is Theorem 6.1, which provides an optimal credibility weight for combining the chain-ladder or individual loss ratio reserve (grossed up latest claims experience of an origin period) with the Bornhuetter-Ferguson or collective loss ratio reserve (experience based burning cost estimate of the total ultimate claims of an origin period). The obtained simple optimal credibility weights minimize simultaneously the mean squared error and the variance of the claims reserve.

The organization of the paper is as follows. Section 2 contains the necessary prerequisites and the definition of the mentioned collective and individual loss ratio claims reserves. Section 3 defines the credible loss ratio claims reserves. Formulas for the optimal credibility weights, which minimize the mean squared errors of the credible loss ratio reserves, as well as formulas for the mean squared errors are derived in Section 4. The practical evaluation of these quantities is based on a pragmatic estimation method, which is motivated in Section 5. In Section 6, the remaining unspecified parameters of the pragmatic estimation method are chosen such that they minimize additionally the variance of the optimal credible claims reserve. This is a desirable property because from a statistical point of view estimates with lower variances are usually preferred. Fortunately, the minimum variance optimal credible claims reserve is parameter-free and comparable in simplicity to the Neuhaus and Benktander loss ratio reserves. Finally, Section 7 presents numerical examples. Based on our pragmatic estimation method, we observe that the Neuhaus and Benktander loss ratio reserves are quite close to the optimal credible reserve. In our examples, the Neuhaus reserve is closer to the optimal one than the Benktander reserve for all origin periods. Through application of a credible loss ratio reserving method, the reduction in mean squared error is substantial. In absence of sufficient information to estimate the optimal credibility weights more precisely, the three simple credible methods are highly recommended for actuarial practice.

2. The collective and individual loss ratio claims reserves

Let \( n \) be the number of origin periods, say one-year periods, for which historical data on paid claims is available. Let \( S_{ik}, 1 \leq i, k \leq n \), be the paid claims from origin period \( i \) reported in period \( i + k - 1 \). Under the assumption that after
development periods all claims incurred in an origin period are known and closed, the amount \( \sum_{i=1}^{n} S_{ik} \) is the total ultimate claims from origin period \( i \). The sums \( C_{ik} = \sum_{j=1}^{i} S_{ij} \), \( 1 \leq i, k \leq n \), denote the accumulated paid claims incurred in calendar year \( i \) and reported after \( i + k - 1 \) years of development. At the end of the current calendar year only the amount \( C_{i,n-i+1} = \sum_{k=1}^{n-i+1} S_{ik} \) is known. The required amount for the incurred but unpaid claims of period \( i \), called \( i \)-th period claims reserve, is equal to \( R_i = \sum_{k=1}^{n} S_{ik} \), \( i = 2, \ldots, n \). The total required amount of incurred but unpaid claims over all periods \( R = \sum_{i=2}^{n} R_i \) is called total claims reserve.

To fix ideas, we suppose that the measure of exposure \( V_i \) is the premium belonging to the origin period \( i = 1, \ldots, n \). Our analysis is based on (expected) loss ratios representing the incremental amount of expected paid claims per unit of premium in each development period, which are defined by

\[
m_k = \frac{E \left[ \sum_{i=1}^{n-k+1} S_{ik} \right]}{\sum_{i=1}^{n-k+1} V_i}, \quad k = 1, \ldots, n.
\]

Since the sum \( \sum_{k=1}^{n} m_k \) represents the loss ratio over all reporting periods, the quantity

\[
E \left[ U_{iBC} \right] = V_i \cdot \sum_{k=1}^{n} m_k
\]

is nothing else than the expected value of the burning cost \( U_{iBC} \) of the total ultimate claims required for the origin period \( i \). This quantity is similar to the expected value of the Bornhuetter-Ferguson prior estimate \( U_0 \) of the total ultimate claims in Mack (2000). By definition of the loss ratios, the quantities \( V_i \cdot \sum_{k=1}^{n-i+1} m_k \), \( i = 1, \ldots, n \), represent the expected burning cost of the paid claims for the origin period \( i \), which are required in the current calendar period. The loss ratio payout factor (also called loss ratio lag-factor) defined by

\[
p_i = \frac{V_i \cdot \sum_{k=1}^{n-i+1} m_k}{E \left[ U_{iBC} \right]} = \frac{\sum_{k=1}^{n-i+1} m_k}{\sum_{k=1}^{n} m_k}, \quad i = 1, \ldots, n,
\]

represents the proportion of the total ultimate claims from origin period \( i \), which is expected to be paid in the development period \( n-i+1 \). The quantity

\[
q_i = 1 - p_i = \frac{\sum_{k=n-i+2}^{n} m_k}{\sum_{k=1}^{n} m_k}, \quad i = 1, \ldots, n,
\]

represents...
called *loss ratio reserve factor*, represents the proportion of the total ultimate claims from origin period \( i \), which remain unpaid in the development period \( n - i + 1 \).

From this an estimate of the total ultimate claims is obtained by grossing up the latest accumulated paid claims amount. Since it is based solely on the individual latest claims experience of an origin period, it is called *individual total ultimate claims amount* and is given by

\[
U_{i}^{\text{ind}} = \frac{C_{i,n-i+1}}{p_i}, \quad i = 1, \ldots, n. \quad (2.5)
\]

This estimate is similar to the chain-ladder estimate in Mack (2000). A corresponding estimate of the claims reserve, called *individual loss ratio claims reserve*, is defined by

\[
R_{i}^{\text{ind}} = U_{i}^{\text{ind}} - C_{i,n-i+1} = q_i \cdot U_{i}^{\text{ind}} = \frac{q_i}{p_i} \cdot C_{i,n-i+1}, \quad i = 1, \ldots, n. \quad (2.6)
\]

On the other side, the burning cost of the total ultimate claims leads to the alternative claims reserve

\[
R_{i}^{\text{coll}} = q_i \cdot U_{i}^{\text{BC}}, \quad U_{i}^{\text{BC}} = V_i \cdot \sum_{k=1}^{n-k+1} S_{ik}, \quad i = 1, \ldots, n. \quad (2.7)
\]

It is called *collective loss ratio claims reserve* because it depends solely on the portfolio claims experience of all origin periods. It coincides with the claims reserve set according to the loss ratio reserving method as defined in Mack (1997), Section 3.2.2, p. 230-234. The associated *collective total ultimate claims* is given by

\[
U_{i}^{\text{coll}} = R_{i}^{\text{coll}} + C_{i,n-i+1}, \quad i = 1, \ldots, n. \quad (2.8)
\]

This estimate is similar to the Bornhuetter-Ferguson posterior estimate of the total ultimate claims in Mack (2000). An advantage of the collective loss ratio claims reserve over the Bornhuetter-Ferguson reserve in Mack (2000) is that different actuaries come always to the same results provided they use the same premiums. This is also true for the individual claims reserve without restriction.

### 3. CREDIBLE LOSS RATIO CLAIMS RESERVES

Like the Bornhuetter-Ferguson and the chain-ladder estimates in Mack (2000), the considered collective and individual loss ratio claims reserve estimates represent extreme positions. Indeed, the individual claims reserve considers the
latest accumulated paid claims amount $C_{i,n-i+1}$ to be fully credible predictive for future claims and ignores the burning cost $U_{i}^{BC}$ of the total ultimate claims, while the collective claims reserve ignores the current accumulated paid claims and relies fully on the burning cost. Therefore it is natural to apply the credibility mixture to those reserves and use the credible loss ratio claims reserve estimate

$$R_{i}^{c} = Z_{i} \cdot R_{i}^{ind} + (1 - Z_{i}) \cdot R_{i}^{coll}, \quad i = 1, \ldots, n,$$

(3.1)

where $Z_{i}$ is the credibility weight associated to the individual loss ratio reserve. It is interesting to reconsider two popular choices of the credibility weights proposed in the literature. As the credibility weight should increase similarly as the accumulated paid claims $C_{i,n-i+1}$ develop, Gunnar Benktander (1976) proposed the credibility weight $Z_{i}^{GB} = p_{i}$, $i = 1, \ldots, n$. This leads to the Benktander loss ratio claims reserve

$$R_{i}^{GB} = p_{i} \cdot R_{i}^{ind} + q_{i} \cdot R_{i}^{coll}, \quad i = 1, \ldots, n.$$  

(3.2)

According to Mack (1997), p. 242, the choice made by Walter Neuhaus (1992) corresponds to the credibility weight $Z_{i}^{WN} = \sum_{k=1}^{n-i+1} m_{k} = p_{i} \cdot \sum_{k=1}^{n} m_{k}$. It leads to the Neuhaus loss ratio claims reserve

$$R_{i}^{WN} = Z_{i}^{WN} \cdot R_{i}^{ind} + (1 - Z_{i}^{WN}) \cdot R_{i}^{coll}, \quad i = 1, \ldots, n.$$  

(3.3)

It is remarkable that in numerical examples these simple choices are both quite close to an optimal credible loss ratio claims reserve, whose credibility weights are derived in Section 6.

On the other side, remarks similar to those made by Mack (2000) at the end of Section 2 can be made. The functions $R_{i}(U_{i}) = q_{i} U_{i}$ and $U_{i}(R_{i}) = R_{i} + C_{i,n-i+1}$ are not inverse to each other except for $U_{i} = U_{i}^{ind}$. Similarly to the “iterated Bornhuetter-Ferguson method”, there is an “iterated collective loss ratio reserving method”. The successive iteration of the collective and Benktander loss ratio reserving methods for an arbitrary start point $U_{i}^{0}$ leads in the infinite limit to the individual loss ratio reserving method. It is worthwhile to restate this result, which paraphrases Theorem 1 in Mack (2000).

**Theorem 3.1.** For an arbitrary starting point $U_{i}^{(0)} = U_{i}^{0}$, the iteration rule

$$R_{i}^{(m)} = q_{i} \cdot U_{i}^{(m)}, \quad U_{i}^{(m+1)} = C_{i,n-i+1} + R_{i}^{(m)}, \quad m = 0, 1, 2, \ldots,$$

(3.4)

gives credibility mixtures

$$U_{i}^{(m)} = (1 - q_{i}^{m}) \cdot U_{i}^{ind} + q_{i}^{m} \cdot U_{i}^{0},$$

$$R_{i}^{(m)} = (1 - q_{i}^{m}) \cdot R_{i}^{ind} + q_{i}^{m} \cdot R_{i}^{0},$$

(3.5)
between the collective and individual loss ratio reserving methods, which starts at the collective method and lead via the Benktander method finally to the individual method for $m = \infty$.

4. THE OPTIMAL CREDIBILITY WEIGHTS AND THE MEAN SQUARED ERROR

In the following, we suppose that the burning cost estimate $U_i^{BC}$, defined in (2.7), of the total ultimate claims is independent from $C_{i,n-i+1}, R_i$ and $U_i = R_i + C_{i,n-i+1}$, and has expectation $E[U_i^{BC}] = E[U_i^{ind}] = E[U_i]$ (usual unbiasedness) and variance $Var[U_i^{BC}]$. This key working assumption is similar to the assumption made to get Theorem 2 in Mack (2000).

Theorem 4.1. The optimal credibility weights $Z_i^*$ which minimize the mean squared error $mse(R_i^c) = E[(R_i^c - R_i)^2]$ is given by

$$Z_i^* = \frac{p_i}{q_i} \cdot \frac{Cov[C_{i,n-i+1}, R_i] + p_i q_i \cdot Var[U_i^{BC}]}{Var[C_{i,n-i+1}] + p_i^2 \cdot Var[U_i^{BC}]}.$$  \hspace{1cm} (4.1)

Proof. By definition (3.1) of the credible loss reserve one has

$$E[(R_i^c - R_i)^2] = E[(Z_i \cdot (R_i^{ind} - R_i^{coll}) + R_i^{coll} - R_i)^2]$$

$$= Z_i^2 \cdot E[(R_i^{ind} - R_i^{coll})^2] - 2Z_i \cdot E[(R_i^{ind} - R_i^{coll})(R_i - R_i^{coll})] + E[(R_i^{coll} - R_i)^2]$$

From the first order condition

$$\frac{\partial}{\partial Z_i} E[(R_i^c - R_i)^2] = 2Z_i \cdot E[(R_i^{ind} - R_i^{coll})^2] - 2 \cdot E[(R_i^{ind} - R_i^{coll})(R_i - R_i^{coll})] = 0,$$

one obtains that

$$Z_i^* = \frac{E[(R_i^{ind} - R_i^{coll})(R_i - R_i^{coll})]}{E[(R_i^{ind} - R_i^{coll})^2]}, \quad i = 1, \ldots, n.$$  \hspace{1cm} (4.2)

Inserting the expressions $R_i^{ind} = q_i \cdot U_i^{ind} = \frac{q_i}{p_i} \cdot C_{i,n-i+1}$ and $R_i^{coll} = q_i \cdot U_i^{BC}$ one gets

$$Z_i^* = \frac{p_i}{q_i} \cdot \frac{Cov[C_{i,n-i+1} - p_i U_i^{BC}, R_i - q_i U_i^{BC}]}{Var[C_{i,n-i+1} - p_i U_i^{BC}]}.$$  \hspace{1cm} (4.3)
By definition (2.5) and the made assumption one has \( E[C_{i,n-i+1}] = p_i E[U_{i}^{\text{ind}}] = p_i E[U_i^{BC}] \), hence \( E[R_i] = E[U_i - C_{i,n-i+1}] = (1 - p_i) \cdot E[U_i^{BC}] = q_i \cdot E[U_i^{BC}] \). Using this and the assumption that \( U_i^{BC} \) is independent from \( C_{i,n-i+1} \), \( R_i \) and \( U_i \), one gets the desired formula (4.1).

To estimate the optimal credibility weights, one needs a model for \( \text{Var}[C_{i,n-i+1}] \) and \( \text{Cov}[C_{i,n-i+1}, R_i] \). Consider the following conditional model for the loss ratio payout (see Mack (2000), p. 338):

\[
E\left[ \frac{C_{i,n-i+1}}{U_i} \middle| U_i \right] = p_i, \quad \text{Var}\left[ \frac{C_{i,n-i+1}}{U_i} \middle| U_i \right] = p_i q_i \beta_i^2(U_i), \quad i = 1, \ldots, n. \tag{4.4}
\]

The factor \( q_i \) ensures that \( \text{Var}\left[ \frac{C_{i,n-i+1}}{U_i} \middle| U_i \right] = 0 \) when \( i = 1 \) and that \( \text{Var}\left[ \frac{C_{i,n-i+1}}{U_i} \middle| U_i \right] \to 0 \) in case of very small values \( p_i \). In the following the notation \( \alpha_i^2(U_i) = U_i^2 \cdot \beta_i^2(U_i) \) is used.

**Theorem 4.2.** Under the assumption of model (4.4), the optimal credibility weights \( Z_i^* \) which minimize the mean squared error \( \text{mse}(R_i) = E[(R_i - R_i)^2] \) is given by

\[
Z_i^* = \frac{p_i}{p_i + t_i}, \quad \text{with} \tag{4.5}
\]

\[
t_i = \frac{E[\alpha_i^2(U_i)]}{\text{Var}[U_i^{BC}] + \text{Var}[U_i] - E[\alpha_i^2(U_i)]}, \quad i = 1, \ldots, n. \tag{4.6}
\]

**Proof.** From (4.4) one obtains

\[
E[C_{i,n-i+1} \middle| U_i] = p_i U_i, \quad \text{Var}[C_{i,n-i+1} \middle| U_i] = p_i q_i \alpha_i^2(U_i), \quad i = 1, \ldots, n. \tag{4.7}
\]

It follows that

\[
\text{Var}[C_{i,n-i+1}] = E[\text{Var}[C_{i,n-i+1} \middle| U_i]] + \text{Var}[E[C_{i,n-i+1} \middle| U_i]]
= p_i q_i E[\alpha_i^2(U_i)] + p_i^2 \text{Var}[U_i]
\tag{4.8}
\]

and

\[
\text{Cov}[C_{i,n-i+1}, U_i] = E[\text{Cov}[C_{i,n-i+1}, U_i \middle| U_i]] + \text{Cov}[E[C_{i,n-i+1} \middle| U_i], U_i] = p_i \text{Var}[U_i]. \tag{4.9}
\]
From (4.8) and (4.9) one obtains further
\[
Cov[C_{i,n-i+1}, R_i] = Cov[C_{i,n-i+1}, U_i] - Var[C_{i,n-i+1}] = p_i q_i \cdot (Var[U_i] - E[\alpha_i^2(U_i)]).
\]
(4.10)

Inserting (4.8) and (4.10) into (4.1) the desired formula follows. □

Simple formulas for the mean squared errors are derived in a similar way.

**Theorem 4.3.** Under the assumption of model (4.4), the following formulas for the mean squared errors hold:

\[
\text{mse}(R_{i}^{\text{coll}}) = E[\alpha_i^2(U_i)] \cdot q_i \left(1 + \frac{q_i}{l_i}\right),
\]
\[
\text{mse}(R_{i}^{\text{ind}}) = E[\alpha_i^2(U_i)] \cdot \frac{q_i}{p_i},
\]
\[
\text{mse}(R_{i}^{c}) = E[\alpha_i^2(U_i)] \cdot \left(\frac{Z_i^2}{p_i} + \frac{1}{q_i} + \frac{(1 - Z_i)^2}{l_i}\right) \cdot q_i^2.
\]
(4.11)

**Proof.** Using (4.8) and (4.9) one obtains

\[
Var[R_i] = Var[U_i - C_{i,n-i+1}] = Var[U_i] - 2Cov[C_{i,n-i+1}, U_i] + Var[C_{i,n-i+1}]
= Var[U_i] \cdot (1 - 2p_i + p_i^2) + p_i q_i E[\alpha_i^2(U_i)] = q_i^2 \cdot Var[U_i] + p_i q_i E[\alpha_i^2(U_i)]
= q_i E[\alpha_i^2(U_i)] + q_i^2 \cdot (Var[U_i] - E[\alpha_i^2(U_i)])
\]
(4.12)

Since \( E[R_{i}^{\text{coll}}] = q_i E[U_{i}^{BC}] = q_i E[U_i] = E[U_i - C_{i,n-i+1}] = E[R_i] \) and by assumption \( Cov[R_{i}^{\text{coll}}, R_i] = q_i Cov[U_{i}^{BC}, R_i] = 0 \), one has

\[
\text{mse}(R_{i}^{\text{coll}}) = E[(R_{i}^{\text{coll}} - R_i)^2] = Var[R_{i}^{\text{coll}} - R_i] = Var[R_{i}^{\text{coll}}] + Var[R_i]
= q_i^2 \cdot Var[U_{i}^{BC}] + q_i^2 \cdot (Var[U_i] - E[\alpha_i^2(U_i)]) + q_i \cdot E[\alpha_i^2(U_i)]
\]
(4.13)

where the last equality follows from (4.6) of Theorem 4.2. Similarly, one has \( E[R_{i}^{\text{ind}}] = E[R_i] \) and it follows that

\[
\text{mse}(R_{i}^{\text{ind}}) = E[(R_{i}^{\text{ind}} - R_i)^2] = Var[R_{i}^{\text{ind}} - R_i] = Var[R_{i}^{\text{coll}}] - 2Cov[R_{i}^{\text{ind}}, R_i] + Var[R_i]
= \left(\frac{q_i}{p_i}\right)^2 \cdot Var[C_{i,n-i+1}] - 2 \frac{q_i}{p_i} Cov[C_{i,n-i+1}, R_i] + Var[R_i].
\]
(4.14)
Inserting (4.8), (4.10) and (4.12) one gets without difficulty the desired formula (4.11). The third formula follows from

\[ mse(R_i) = E[ (Z_i (R_i^{ind} - R_i) + (1 - Z_i)(R_i^{coll} - R_i))^2 ] \]  
\[ = Z_i^2 mse(R_i^{ind}) + 2Z_i(1 - Z_i) E[(R_i^{ind} - R_i)(R_i^{coll} - R_i)] + (1 - Z_i)^2 mse(R_i^{coll}), \]

and

\[ E[(R_i^{ind} - R_i)(R_i^{coll} - R_i)] = Cov[R_i^{ind} - R_i, R_i^{coll} - R_i] = Var[R_i] - Cov[R_i^{ind}, R_i] \]
\[ = Var[R_i] - \frac{q_i}{p_i} Cov[C_{i,n-i+1}, R_i] = q_i E[\alpha_i^2(U_i)] \] 
using the formulas for \( mse(R_i^{ind}) \) and \( mse(R_i^{coll}) \).

\[ 5. \text{ A PRAGMATIC ESTIMATION METHOD} \]

To evaluate the optimal credibility weights and the mean squared errors, it is necessary to estimate the quantities \( Var[U_i^{BC}], Var[U_i] \) and \( E[\alpha_i^2(U_i)] \). The proposed estimators are based on a full loss triangle of paid claims statistics \( S_{ik}, 1 \leq i, k \leq n \), subject to the restriction \( i + k - 1 \leq n \), and the knowledge of exposures \( V_i \) for each origin period \( i = 1, \ldots, n \). Working in an unconditional environment we use the following standard estimate for \( Var[U_i^{BC}] \), which follows from the analysis by Mack (1997), p. 231-233:

\[ \hat{Var}[U_i^{BC}] = V_i^2 \cdot \left( \sum_{k=1}^{n} \frac{s_k^2}{w_k} \right), \text{ with} \] 
\[ w_k = \sum_{i=1}^{n-k+1} V_i, \quad s_k^2 = \frac{1}{n-k} \sum_{i=1}^{n-k+1} V_i \left( \frac{S_{ik}}{V_i} - \hat{m}_k \right)^2, \] 
\[ \hat{m}_k = \frac{\sum_{i=1}^{n-k+1} S_{ik}}{\sum_{i=1}^{n-k+1} V_i}, \quad k = 1, \ldots, n-1, \quad s_n^2 = \min \{ s_k^2 | k = 1, \ldots, n-1 \} \]

It is intuitively appealing that \( U_i \) should be at least as volatile than the burning cost estimate \( U_i^{BC} \) (similar to the fact that \( Var[U] \) should be larger than \( Var[U_0] \) in Mack (2000)). As pragmatic estimates we assume that

\[ \hat{Var}[U_i] = f_i \cdot \hat{Var}[U_i^{BC}], \quad \hat{E}[U_i] = U_i^{BC}, \]
with some factor $f_i \geq 1$, and that an estimate of $\beta_i^2(U_i)$ in (4.4) is a constant $\beta_i^2$ for all underwriting periods $i = 1, \ldots, n$. The quantities $f_i$ and $\beta_i$ can be statistically justified as follows. Arguing that $U_i^{BC}$ is a good unbiased point estimate of the total ultimate claims, it is reasonable to assume that $U_i$ belongs to the confidence interval $\left[ U_i^{BC} - c_i \cdot \sqrt{\text{Var}[U_i^{BC}]}, U_i^{BC} + c_i \cdot \sqrt{\text{Var}[U_i^{BC}]} \right]$ for some constant $c_i > 1$. On the other side $U_i$ should belong to the confidence interval $\left[ \hat{E}[U_i] - d_i \cdot \sqrt{\text{Var}[U_i]}, \hat{E}[U_i] + d_i \cdot \sqrt{\text{Var}[U_i]} \right]$ for some constant $d_i \leq c_i$ ($U_i$ at least as volatile than $U_i^{BC}$). If $\hat{E}[U_i] = U_i^{BC}$, one must have $\text{Var}[U_i] = f_i \cdot \text{Var}[U_i^{BC}]$ for some constant $f_i \geq 1$. On the other side, if the ratio $C_{i,n-i+1} / U_i$ given $U_i$ has a Beta($a_i, p_i$) distribution with some constant $a_i > 0$, then one has necessarily $\beta_i^2(U_i) = (a_i + 1)^{-1}$, which is a constant independent of $U_i$. Recalling that $\alpha_i^2(U_i) = U_i^2 \cdot \beta_i^2(U_i)$, one obtains from (5.3) the following estimate

$$\hat{E}[\alpha_i^2(U_i)] = \beta_i^2 \cdot \left\{ f_i \cdot \text{Var}[U_i^{BC}] + (U_i^{BC})^2 \right\}. \quad (5.4)$$

The above estimates are inserted in the formulas of Theorems 4.2 and 4.3 to get estimates of the optimal credibility weights and the mean squared errors. In particular, an optimal credibility estimate is obtained from

$$\hat{\beta}_i = \frac{\beta_i^2 \cdot (f_i + \hat{u})}{1 + f_i - \beta_i^2 \cdot (f_i + \hat{u})}, \quad (5.5)$$

where $\hat{u} = \left( \frac{U_i^{BC}}{\text{Var}[U_i^{BC}]} \right)^2 = \frac{\left( \sum_{k=1}^{n} \hat{m}_k \right)^2}{\sum_{k=1}^{n} \frac{s_k^2}{w_k}}$ is an estimate of the inverse of the coefficient of variation of the burning cost estimate $U_i^{BC}$ of the total ultimate claims, which is independent of the origin period.

6. THE OPTIMAL CREDIBLE CLAIMS RESERVE WITH MINIMUM VARIANCE

The pragmatic estimation method of Section 5 depends on the unknown parameters $(f_i, \beta_i)_{1 \leq i \leq n}$. As in the preceding Section, we work in an unconditional framework and compare the variances of the individual, collective and optimal credible claims reserves in order to determine a set of parameters $(f_i, \beta_i)_{1 \leq i \leq n}$, which minimizes the variance of the optimal credible claims reserve. This is a desirable property because from a statistical point of view estimates with lower variances are usually preferred. Fortunately, the minimum variance optimal credible claims reserve is parameter-free and attained at the parameter value

$$t_i^* = \sqrt{p_i}, \quad i = 1, \ldots, n, \quad (6.1)$$
in Theorem 4.2. It compares with the Benktander estimate
\[ t_i^{GB} = q_i, \quad i = 1, \ldots, n, \]  
(6.2)
and the Neuhaus estimate
\[ t_i^{WN} = q_i + \frac{1 - \sum_{k=1}^{n} m_k}{\sum_{k=1}^{n} m_k}, \quad i = 1, \ldots, n. \]  
(6.3)

All three methods yield monotone decreasing credibility weights in the origin periods. Since \( t_i^* = 1 \) the optimal credibility weights satisfy the inequality
\[ Z_i^* \leq \frac{1}{2}, \quad i = 1, \ldots, n, \]  
(6.4)
where the equality is attained for the first origin period. Note that usually the Benktander and Neuhaus methods lead to higher credibility weights. The proposed new method is the special case \( f_i = 1 \) of the following more general result. This choice, which implies identical volatilities for \( U_i \) and \( U_i^{BC} \), is the most appealing one. Besides the minimum variance of the credible loss reserves among all choices \( f_i \geq 1 \), it yields the smallest credibility weights for the individual loss reserves putting thus more emphasis on the collective loss reserves.

**Theorem 6.1.** Under the assumption of Sections 4 and 5, the optimal credibility weights \( Z_i^* \) which minimize the mean squared error \( mse(R_i^c) = E[(R_i^c - R_i)^2] \) and the variance \( Var[R_i^c] \) are given by
\[ Z_i^* = \frac{p_i}{p_i + t_i^*}, \quad \text{with} \]  
\[ t_i^* = \frac{f_i - 1 + \sqrt{(f_i + 1) \cdot (f_i^2 - 1 + 2 \cdot p_i)}}{2}, \quad i = 1, \ldots, n. \]  
(6.6)

**Proof.** Recall that \( R_i^c = Z_i \cdot R_i^\text{ind} + (1 - Z_i) \cdot R_i^\text{coll}, \quad i = 1, \ldots, n, \) with \( R_i^\text{ind} = \frac{q_i}{p_i} \cdot C_{i,n-i+1}, \) \( R_i^\text{coll} = q_i \cdot U_i^{BC} \). By the assumption at the beginning of Section 4, the covariance between the individual and the collective reserve vanishes, that is \( Cov[R_i^\text{ind}, R_i^\text{coll}] = \frac{q_i}{p_i} \cdot Cov[C_{i,n-i+1}, U_i^{BC}] = 0 \). It follows that
\[ Var[R_i^c] = Z_i^2 \cdot Var[R_i^\text{ind}] + (1 - Z_i)^2 \cdot Var[R_i^\text{coll}], \quad \text{with} \]  
\[ Var[R_i^\text{ind}] = \left(\frac{q_i}{p_i}\right)^2 \cdot Var[C_{i,n-i+1}], \quad Var[R_i^\text{coll}] = q_i^2 \cdot Var[U_i^{BC}]. \]
Using (4.8) and the estimates (5.3), (5.4) and the definition of $\hat{u}$ after (5.5), one gets the estimate

$$\widehat{\text{Var}}[C_{i,n-i+1}] = (f_i \cdot p_i \cdot [(1-p_i)\beta_i^2 + p_i] + p_i(1-p_i)\beta_i^2 \hat{u}) \cdot \text{Var}[U_{i}^{BC}] .$$

Inserted into the above formulas, together with the estimate $\hat{Z}_i = \frac{p_i}{p_i + \hat{t}_i}$ of the optimal credibility weight (4.5), one obtains the estimate

$$\widehat{\text{Var}}[R_i^c] = \hat{Z}_i^2 \cdot \left( \frac{q_i}{p_i} \right)^2 [f_i \cdot p_i \cdot [(1-p_i)\beta_i^2 + p_i] + p_i(1-p_i)\beta_i^2 \hat{u}]$$

$$\cdot \text{Var}[U_{i}^{BC}] + (1 - \hat{Z}_i)^2 \cdot \text{Var}[R_i^{coll}]$$

$$= \left( \hat{Z}_i^2 \cdot \left[ f_i + \frac{1-p_i}{p_i} \beta_i^2 (f_i + \hat{u}) \right] + (1 - \hat{Z}_i)^2 \right) \cdot \text{Var}[R_i^{coll}] .$$

From (5.5) one has $\beta_i^2 (f_i + \hat{u}) = (1 + f_i) \frac{\hat{t}_i}{1 + \hat{t}_i}$, which yields further

$$\widehat{\text{Var}}[R_i^c] = \left( \hat{Z}_i^2 \cdot (1 + f_i) \cdot \left[ 1 + \frac{1-p_i}{p_i} \frac{\hat{t}_i}{1 + \hat{t}_i} \right] - 2 \hat{Z}_i + 1 \right) \cdot \text{Var}[R_i^{coll}]$$

$$= \left( 1 - \frac{2\hat{t}_i - (f_i - 1)}{1 + \hat{t}_i} \cdot \frac{p_i}{p_i + \hat{t}_i} \right) \cdot \text{Var}[R_i^{coll}] .$$

An optimization with respect to $\hat{t}_i$ shows that the minimum variance is attained at (6.6). \hfill \square

**Remark 6.1.**

An important difference with the standard approach to claims reserving must be emphasized. Though in Mack (2000) the meaning of the payout factor $p_i$ is general, in practice it has up to now most often been estimated using standard link ratios leading to *chain-ladder payout or lag-factors* $p_i^{CL}$ instead of the loss ratio based factors (2.3). Clearly, our main result can also be reused in the traditional as well as more advanced and recent stochastic chain-ladder context. In practice, the standard methods use the so-called *chain-ladder factors* defined by the average link ratios (here by abuse of stochastic notation as statistical estimates)

$$f_k^{CL} = \sum_{i=1}^{n-k} S_{ik} + 1 / \sum_{i=1}^{n-k} S_{ik}, \quad k = 1, \ldots, n-1 .$$

From this one gets the ultimate loss development factors, so-called *LDF paid factors.*
which represent the average ratio of the ultimate claims to the (cumulative) paid claims of each origin period after \( k \) years of development. From the LDF paid factors one gets immediately the chain-ladder lag-factors

\[
p_{i}^{CL} = \frac{1}{F_{n-i+1}^{CL}}, \quad i = 1, \ldots, n, \tag{6.9}
\]

and the chain-ladder reserve factors

\[
q_{i}^{CL} = 1 - p_{i}^{CL}, \quad i = 1, \ldots, n. \tag{6.10}
\]

The standard methods can be reinterpreted in our context and extended to optimal credible standard methods as follows.

**The Chain-Ladder Method**

It is similar to the individual loss ratio method with the loss ratio lag-factors (2.3) replaced by the chain-ladder lag-factors (6.9):

\[
R_{i}^{CL} = q_{i}^{CL} \cdot C_{i,n-i+1}, \quad i = 1, \ldots, n. \tag{6.11}
\]

**The Cape Cod Method**

It is a (Benktander type) credibility mixture of the type (3.1) with

\[
R_{i}^{ind} = q_{i}^{CL} \cdot C_{i,n-i+1}, \quad R_{i}^{coll} = q_{i}^{CL} \cdot LR \cdot V_{i}, \quad LR = \frac{\sum_{i=1}^{n} C_{i,n-i+1}}{\sum_{i=1}^{n} p_{i}^{CL} \cdot V_{i}}, \tag{6.12}
\]

\[
Z_{i} = p_{i}^{CL}, \quad i = 1, \ldots, n.
\]

**The Optimal Cape Cod Method**

It is the modified credibility mixture (6.12) with optimal credibility weights

\[
Z_{i} = \frac{p_{i}^{CL}}{p_{i}^{CL} + \sqrt{p_{i}^{CL}}}, \quad i = 1, \ldots, n. \tag{6.13}
\]

**The Bornhuetter-Ferguson Method**

It is a (Benktander type) credibility mixture of the type (3.1) with
\[ R^{\text{ind}}_i = \frac{q^{\text{CL}}_i}{p^{\text{CL}}_i} \cdot C_{i,n-i+1}, \quad R^{\text{coll}}_i = q^{\text{CL}}_i \cdot LR_i \cdot V_i, \quad Z_i = p^{\text{CL}}_i, \quad i = 1, \ldots, n, \quad (6.14) \]

where \( LR_i \) is some selected initial loss ratio for each origin period (e.g. Boulter and Grubbs (2000), p. 19-21).

**The Optimal Bornhuetter-Ferguson Method**

It is the modified credibility mixture (6.14) with optimal credibility weights (6.13).

7. **Numerical Examples**

It is instructive to illustrate the obtained results at some practical examples. Let us start with the published full loss triangle of paid claims and exposures in Mack (1997), Table 3.1.5.1:

**TABLE 7.1**

<table>
<thead>
<tr>
<th>Origin period</th>

</table>
The Neuhaus and Benktander loss ratio reserves are quite close to the optimal credible reserve. In the present situation, the Neuhaus reserve is closer to the optimal one than the Benktander reserve for all origin periods. Through application of a credible loss ratio reserving method, the reduction in mean squared error is substantial. In absence of sufficient information to estimate the optimal credibility weights, the three simple credible methods are highly recommended for actuarial practice.

The next practical example stems from a slightly modified real life project. The same conclusions as before are made. Again, the minimum variance estimator of Section 6 is applied with \( f_i = 1 \) and \( t_i = \sqrt{p_i} \).
